

SENSOR WITH FAILURE THRESHOLD

BACKGROUND OF THE INVENTION

Field of the Invention

The present invention relates to an inertial sensor with failure
5 threshold.

Description of the Related Art

As is known, modern techniques of micromachining of
semiconductors can be advantageously exploited for making various extremely
sensitive and precise sensors, having further small overall dimensions. The so-
10 called MEMS sensors (or micro-electro-mechanical-system sensors), are sensors
that can be integrated in a semiconductor chip and are suitable for detecting
various quantities. In particular, both linear and rotational MEMS accelerometers
with capacitive unbalancing are known. In brief, these accelerometers are
normally provided with a fixed body and of a mobile mass, both of which are
15 conductive and are capacitively coupled together. In addition, the capacitance
present between the fixed body and the mobile mass may vary, and its value
depends upon the relative position of the mobile mass with respect to the fixed
body. When the accelerometer is subjected to a stress, the mobile mass is
displaced with respect to the fixed body and causes a variation in the coupling
20 capacitance, which is detected by a special sensing circuit.

As mentioned previously, MEMS accelerometers are extremely
sensitive and precise; however, they are not suitable for being used in many
applications, mainly because they are complex to make and their cost is very high.
On the one hand, in fact, the processes of fabrication involve the execution of
25 numerous non-standard steps and/or the use of non-standard substrates (for
example, SOI substrates); on the other hand, it is normally necessary to provide

feedback sensing circuits based upon differential charge amplifiers, the design of which frequently involves some difficulties.

In addition, in many cases the precision of capacitive MEMS sensors is not required and, indeed, it is not even necessary to have an instantaneous measurement of the value of acceleration. On the contrary, it is frequently just necessary to verify whether a device incorporating the accelerometer has undergone accelerations higher than a pre-set threshold, normally on account of impact. For example, the majority of electronic devices commonly used, such as cell phones, are protected by a warranty, which is no longer valid if any malfunctioning is due not to defects of fabrication but to an impact consequent on the device being dropped onto an unyielding surface or in any case on a use that is not in conformance with the instructions. Unless visible damage is found, such as marks on the casing or breaking of some parts, it is practically impossible to demonstrate that the device has suffered damage that invalidates the warranty. On the other hand, portable devices, such as cell phones, exactly, are particularly exposed to being dropped and consequently to getting broken, precisely on account of how they are used.

Events of the above type could be easily detected by an inertial sensor, which is able to record accelerations higher than a pre-set threshold. However, the use of MEMS accelerometers of a capacitive type in these cases would evidently lead to excessive costs. It would thus be desirable to have available sensors that can be made using techniques of micromachining of semiconductors, consequently having overall dimensions comparable to those of capacitive MEMS sensors, but simpler as regards both the structure of the sensor and the sensing circuit. In addition, also the processes of fabrication should be, as a whole, simple and inexpensive.

BRIEF SUMMARY OF THE INVENTION

The purpose of the present invention is to provide an inertial sensor with failure threshold, which will enable the problems described above to be overcome.

5 According to the present invention, an inertial sensor with failure threshold is provided, having a first body and a second body, which are moveable relative to one another and are constrained by a plurality of elastic elements, and a first sample element connected between the first body and the second body and shaped so as to be subjected to a stress when the second body is outside of a
10 relative resting position with respect to the first body, and having at least one weakened region. The weakened region may include a narrowing of the first sample element.

 The sensor may also include a second sample element connected between the first and second body and also shaped so as to be subjected to a
15 stress when the second body is outside of a relative resting position with respect to the first body.

 According to another embodiment of the invention, a device is provided, including a semiconductor material substrate, a sample element having a first end coupled to the substrate and configured to break under a preselected
20 strain, and a semiconductor material body coupled to a second end of the sample element.

 The sample element of the device may include a weakened region configured to break under the preselected strain. The weakened region may be formed by a narrowed region of the sample element.

25 According to another embodiment, A cellular telephone or other electronic device is provided, including an inertial sensor configured to permanently change the conductive properties of a conductive path in response to a preselected acceleration, and a circuit configured to detect a change in the conductive properties of the conductive path.

The inertial sensor may comprise a sample element configured to break in response to the preselected acceleration, with the conductive path passing through the sample element.

5 The sample element may be formed of semiconductor material, with a first end coupled to a semiconductor substrate and a second end coupled to a semiconductor material body; the semiconductor body coupled to the semiconductor substrate via spring elements such that the body is free to move relative to the substrate in response to acceleration of the cellular telephone.

10 The preselected acceleration may be selected to be less than or equal to an acceleration sufficient to damage the cellular telephone.

BRIEF DESCRIPTION OF THE SEVERAL VIEWS OF THE DRAWINGS

For a better understanding of the invention, some embodiments thereof are now described, purely by way of non-limiting examples and with reference to the attached drawings, in which:

15 Figures 1 and 2 are cross-sectional views through a semiconductor wafer in successive steps of fabrication;

Figure 3 is a top plan view of the wafer of Figure 2;

Figure 4 illustrates an enlarged detail of Figure 3;

20 Figure 5 is a cross-sectional view of the wafer of Figure 3 in a subsequent fabrication step;

Figure 6 is a top plan view of the wafer of Figure 5;

Figures 7 and 8 are cross-sectional views of the wafer of Figure 6 in a subsequent fabrication step, taken along the planes of trace VII-VII and VIII-VIII, respectively, of Figure 6;

25 Figure 9 is a top plan view of the wafer of Figure 7, incorporating an inertial sensor according to a first embodiment of the present invention;

Figures 10 and 11 are cross-sectional views of the wafer of Figure 9, taken along the planes of trace X-X and XI-XI, respectively, of Figure 9;

Figures 12 and 13 are cross-sectional views through a composite wafer and a die, respectively, obtained starting from the wafer of Figure 9;

DETAILED DESCRIPTION OF THE INVENTION

With reference to Figures 1-13, a wafer 1 of semiconductor material, for example monocrystalline silicon, comprises a substrate 2, on which a thin pad oxide layer 3, for example 2.5 μm thick, is thermally grown. A conductive layer 5 of polysilicon, having for example a thickness of between 400 and 800 nm and a dopant concentration of 10^{19} atoms/cm³, is then deposited on the pad oxide layer 3 and is defined by means of a photolithographic process. Two T-shaped samples 6 are thus obtained, having respective feet 6a, aligned with respect to one another and extending towards one another, and respective arms 6b parallel to one another (Figures 2-4). The feet 6a and the arms 6b of each sample 6 are set in directions identified by a first axis X and, respectively, by a second axis Y, which are mutually orthogonal (a third axis Z, orthogonal to the first axis X and the second axis Y, is illustrated in Figure 2). In addition, at respective ends of the arms 6b of both the samples 6 anchoring pads 8 are made, of a substantially rectangular shape and having a width greater than the arms 6b. As illustrated in Figure 4, each of the samples 6 has a first weakened region 9 and a second weakened region 10. In particular, in both of the samples 6, the first weakened region 9 and the second weakened region 10 are made as narrowed portions of the foot 6a and, respectively, of one of the arms 6b. In addition, the weakened regions 9, 10 are defined by notches 11 with a circular or polygonal profile, made in an area of joining 6c between the foot 6a and the arms 6b and traversing the sample 6 in a direction parallel to the third axis Z. The thickness of the conductive layer 5 of polysilicon, the dimensions of the feet 6a and of the arms 6b of the

samples 6, and the conformation of the weakened regions 9, 10 determine the mechanical resistance to failure of the samples 6 themselves. In particular, acting on the shape and on the dimensions of the notches 11 defining the first weakened region 9 and the second weakened region 10, it is possible to obtain pre-set failure thresholds of the samples 6 along the first, second and third axes X, Y and Z. Preferably, all the mechanical failure thresholds are basically the same.

Next, a sacrificial layer 12 of silicon dioxide is deposited so as to coat the pad oxide layer 3 and the samples 6. In practice, the pad oxide layer 3 and the sacrificial layer 12 form a single sacrificial region in which the samples 6 are embedded. The sacrificial layer 12 is then defined by means of a photolithographic process comprising two masking steps. During a first step, first openings 14 are made in the sacrificial layer 12, exposing respective ends of the feet 6a of the samples 6, as illustrated in Figure 5. In a second step of the photolithographic process (Figure 6), both the sacrificial layer 12 and the pad oxide layer 3 are selectively etched, so as to make second openings 15, exposing portions of the substrate 2.

Subsequently, a conductive epitaxial layer 16 is grown on the wafer 1, the said layer having a thickness, for example, of 15 μm and a dopant concentration of 10^{18} atoms/cm³. In detail, the epitaxial layer 16 coats the sacrificial layer 12 entirely and extends in depth through the first and the second openings 14, 15 until the samples 6 and the substrate 2, respectively, are reached (Figure 7 and 8).

The epitaxial layer 16 is then selectively etched, preferably by reactive-ion etching (RIE), and the sacrificial layer 12 and the pad oxide layer 3 are removed. In greater detail, during the step of etching of the epitaxial layer 16, the following are formed: a mobile mass 18; anchorages 19, provided on the portions of the substrate 2 previously exposed by the second openings 15; a plurality of springs 20, connecting the mobile mass 18 to the anchorages 19; and a ring-shaped supporting structure 21, which surrounds the mobile mass 18, the samples

6, the springs 20, and the corresponding anchorages 19 (see Figure 9, in which the sacrificial layer 12 and the pad oxide layer 3 have already been removed).

The mobile mass 18 is connected to the substrate 2 by the springs 20, which are in turn constrained to the anchorages 19 (Figure 11). The springs 20, which are per se known, are shaped so as to enable oscillations of the mobile mass 18 with respect to the substrate 2 along each of the three axes X, Y, Z, at the same time, however, preventing rotations. The mobile mass 18 is moreover constrained to the substrate 2 through the samples 6. In greater detail, the mobile mass 18 has, in a median portion, a pair of anchoring blocks 22, projecting outwards in opposite directions along the second axis Y. The anchoring blocks 22 are connected to the end of the foot 6a of a respective one of the samples 6, as illustrated in Figure 10. In turn, the samples 6 are anchored to the substrate 2 through the anchoring pads 8. By controlling the duration of etching of the sacrificial layer 12 and of the pad oxide layer 3, the silicon dioxide is in fact removed only partially underneath the anchoring pads 8, which are wider than the feet 6a and the arms 6b of the samples 6; thus, residual portions 3' of the pad oxide layer 3, which are not etched, fix the anchoring pads 8 to the substrate 2, serving as bonding elements.

The sacrificial layer 12 and the remaining portions of the pad oxide layer 3 are, instead, completely removed and, hence, the mobile mass 18 and the samples 6 are freed. In practice, the mobile mass 18 is suspended at a distance on the substrate 2 and can oscillate about a resting position, in accordance with the degrees of freedom allowed by the springs 20 (in particular, it can translate along the axes X, Y and Z). Also the samples 6 are elastic elements, which connect the mobile mass 18 to the substrate 2 in a way similar to the springs 20. In particular, the samples are shaped so as to be subjected to a stress when the mobile mass 18 is outside a relative resting position with respect to the substrate 2. The samples 6 are, however, very thin and have preferential failure points in areas corresponding to the weakened regions 9, 10. For this reason, their

mechanical resistance to failure is much lower than that of the springs 20, and they undergo failure in a controlled way when they are subjected to a stress of pre-set intensity.

In practice, at this stage of the process, the mobile mass 18, the
5 substrate 2, the springs 20 with the anchorages 19, and the samples 6 form an inertial sensor 24, the operation of which will be described in detail hereinafter.

An encapsulation structure 25 for the inertial sensor 24 is then applied on top of the wafer 1, forming a composite wafer 26 (Figure 12). In particular, the encapsulation structure 25 is an additional semiconductor wafer, in
10 which a recess 27 has previously been opened, in a region that is to be laid on top of the mobile mass 18. The encapsulation structure 25 is coupled to the ring-shaped supporting structure 21 by the interposition of a layer of soldering 29. Next, the compound wafer 26 is cut into a plurality of dice 30, each die comprising an inertial sensor 24 and a respective protective cap 31, formed by the fractioning
15 of the encapsulation structure 25 (Figure 13).

The die 30 is finally mounted on a device 32, for example a cell phone. Preferably, the device 32 is provided with a casing 33, inside which the die 30 is fixed, as illustrated in Figure 14. In addition (Figure 15), the inertial sensor 24 is connected to terminals of a testing circuit 35, which measures the value of
20 electrical resistance between said terminals. In greater detail, the anchoring pads 8 of the arms 6b, in which the second weakened regions 10 are formed, are connected each to a respective terminal of the testing circuit 35.

In normal conditions, *i.e.*, when the inertial sensor 24 is intact, the samples 6 and the mobile mass 18 form a conductive path that enables passage
25 of current between any given pair of anchoring pads 8. In practice, the testing circuit 35 detects low values of electrical resistance between the anchoring pads 8 which is connected to. During normal use, the device 32 undergoes modest stresses, which cause slight oscillations of the mobile mass 18 about the resting position, without jeopardizing the integrity of the inertial sensor 24.

When the device 32 suffers a shock, the mobile mass 18 of the inertial sensor 24 undergoes a sharp acceleration and subjects the samples 6 and the springs 20 to a force. According to the intensity of the stress transmitted to the inertial sensor 24, said force can exceed one of the thresholds of mechanical failure of the samples 6, which consequently break. In particular, failure occurs at one of the weakened regions 9, 10, which have minimum strength. In either case, the conductive path between the two anchoring pads 8 connected to the testing circuit 35 is interrupted, and hence the testing circuit detects a high value of electrical resistance between its own terminals, thus enabling recognition of the occurrence of events that are liable to damage the device 32.

According to a variant of the embodiment described, shown in Figure 16, T-shaped samples 37 are provided, which present a single weakened region 38. In particular, the weakened region 38 is a narrowed portion defined by a pair of notches 39, which are oblique with respect to a foot 37a and arms 37b of the samples 37.

According to a further variant, illustrated in Figures 17 and 18, the two T-shaped samples 6 are located in a gap 36 between the substrate 2 and the mobile mass 18 and have the end of the respective feet 6a in mutual contact. In addition, both of the samples 6 are fixed to a single anchoring block 22' set centrally with respect to the mobile mass 18 itself.

From the above discussion, it is clear that the invention has several advantages. In the first place, the inertial sensor described above has contained overall dimensions. In inertial sensors, in fact, the largest encumbrance is generally due to the mobile mass, which must ensure the necessary precision and sensitivity. In this case, it is sufficient that, in the event of a predetermined acceleration, the mobile mass will cause failure of the weakened regions of the samples, which have low strength. It is consequently evident that also the mobile mass may have contained overall dimensions. In addition, the failure threshold of the samples can easily be controlled via sizing of the weakened regions.

Moreover, the number of electrodes required is much smaller, as compared to inertial sensors of a capacitive type, and hence the overall dimensions can be further reduced.

The inertial sensor according to the invention can be also produced resorting to a process that is simple, has a high yield and, hence, has a very low cost. In fact, processing steps that are standard in the microelectronics industry are employed, such as steps of deposition of layers of both insulating and conductive material, photolithographic processes, a step of epitaxial growth, and standard steps of etching of the epitaxial silicon and of the insulating layers. Advantageously, a single step of thermal oxidation is carried out, and consequently the wafer housing the sensor is subjected to only modest stresses during the fabrication process. In addition, the inertial sensor is obtained starting from a standard, low-cost substrate.

Consequently, sensors of the type described above are particularly suitable for being used in cases where small overall dimensions and contained cost are more important requirements than precision, for example, when it is necessary to record the occurrence of stresses that are harmful for a device in which they are incorporated and in which it is superfluous to provide precise measurements of accelerations. In particular, they can be advantageously used for verifying the validity of the warranty in the case of widely used electronic devices, such as, for example, cell phones.

The use of a single anchoring point between the samples and the mobile mass, as illustrated in the second variant of Figures 17 and 18, has a further advantage as compared to the ones already pointed out, because it enables more effective relaxation of the stresses due to expansion of the materials. In particular, it may happen that the polysilicon parts which are even only partially embedded in the silicon dioxide (samples and portions of the epitaxial layer) will be subjected to a compressive force, since both the polysilicon, and the oxide tend to expand in opposite directions during the fabrication process. When

the oxide is removed, the action of compression on the polysilicon is eliminated, and the polysilicon can thus expand. Clearly, the largest expansion, in absolute terms, is that of the mobile mass, since it has the largest size. The use of a single anchoring point, instead of two anchorages set at a distance apart enables more effective relaxation of the stresses due to said expansion, since the mobile mass can expand freely, without modifying the load state of the samples.

The inertial sensors described are furthermore advantageous because they respond in a substantially isotropic way to the mechanical stress. In practice, therefore, just one inertial sensor is sufficient to detect forces acting in any direction.

A second embodiment of the invention is illustrated in Figures 18 and 19, where parts that are the same as the ones already illustrated are designated by the same reference numbers. According to said embodiment, an inertial sensor 40 is provided with L-shaped samples 41. As in the previous case, the samples 41 are obtained by shaping a conductive polysilicon layer deposited on top of a pad oxide layer (not illustrated herein), which has in turn been grown on the substrate 42 of a semiconductor wafer 43. Using processing steps similar to the ones already described, the mobile mass 18, the anchorages 19 and the springs 20 are subsequently obtained.

In detail, the samples 41 have first ends connected to respective anchoring blocks 22 of the mobile mass 18, and second ends terminating with respective anchoring pads 41 fixed to the substrate 2, as explained previously. In addition, notches 42 made at respective vertices 43 of the samples 41 define weakened regions 44 of the samples 40.

Figures 21 and 22 illustrate a third embodiment of the invention, according to which an inertial sensor 50, made on a substrate 54, comprises samples 51 which are substantially rectilinear and parallel to the first axis X. In this case, during the RIE etching step, in addition to the mobile mass 18, two anchorages 52 and two springs 53 of a known type are provided, which connect

the mobile mass 18 to the anchorages 52 and are shaped so as to prevent substantially the rotation of the mobile mass 18 itself about the first axis X.

The samples 51 have first ends soldered to respective anchoring blocks 22 of the mobile mass 18 and second ends terminating with anchoring pads 55, made as described previously. In addition, pairs of transverse opposed notches 57 define respective weakened regions 58 along the samples 51 (Figure 22).

The inertial sensor 50 responds preferentially to stresses oriented according to a plane orthogonal to the samples 51, *i.e.*, the plane defined by the second axis Y and by the third axis Z. In this case, to detect stresses in a substantially isotropic way, it is possible to use two sensors 50 connected in series between the terminals of a testing circuit 59 and rotated through 90° with respect to one another, as illustrated in Figure 23.

Figures 24-28 show steps of fabrication of an inertial sensor 80, according to a fourth embodiment of the invention, and comprising a substrate 61 a semiconductor wafer 60, a mobile mass 71 and a sample 64, in addition to anchorages 72 and springs 73. At the beginning, a pad oxide layer 62 is grown on the substrate 61; next, a conductive layer 63 of polycrystalline silicon (here indicated by a dashed line) is deposited on the pad oxide layer 61 and is defined to form the sample 64, which is substantially rectilinear and extends parallel to the first axis X (Figure 25). The sample 64 has an anchoring pad 65 at one of its ends and has a weakened region 66 defined by a pair of notches 67 in a central position.

A sacrificial layer 69 of silicon dioxide is deposited so as to coat the entire wafer 60 and is then selectively removed to form an opening 68 at one end of the sample 64 opposite to the anchoring pad 65.

An epitaxial layer 70 is then grown (Figure 26), which is etched so as to form the mobile mass 71; the anchorages 72, the springs 73, and a supporting ring (not illustrated for reasons of convenience). The epitaxial layer extends into

the opening 68 to form a connection region 88 between the sample 64 and the mobile mass 71. The sacrificial layer 69 and the pad oxide layer 62 are removed, except for a residual portion 62' of the pad oxide layer 62 underlying the anchoring pad 65 (Figures 27 and 28). The mobile mass 71 and the sample 64 are thus freed. More precisely, the mobile mass 71, which has, at its center, a through opening 74 on top of the sample 64, is constrained to the substrate 61 through the anchorages 72 and the springs 73, which are shaped so as to prevent any translation along or rotation about the first axis X. In addition, the sample 65 has opposite ends, one connected to the substrate 2 through the anchoring pad 65, and the other to the mobile mass 71 at connection region 88, and is placed in a gap 76 comprised between the mobile mass 71 and the substrate 61.

The inertial sensor 80 is then encapsulated through steps similar to the ones described with reference to Figures 12 and 13.

Also in this case, the use of a single anchoring point between the sample and the mobile mass advantageously enables effective relaxation of the stresses due to expansion of the mobile mass.

According to one variant (not illustrated), the sample is T-shaped, like the ones illustrated in Figure 9.

Figure 29 illustrates a detail of a sample 81, for example a rectilinear one, of an inertial sensor according to a fifth embodiment of the invention. In particular, the sample 81 has a weakened region defined by a transverse groove 82 extending between opposite sides 83 of the sample 81.

The groove 82 is obtained by means of masked etching of controlled duration of the sample 81 (Figure 30).

Alternatively (Figure 31), a first layer 85 of polysilicon is deposited and defined. Then, a stop layer 86 of silicon dioxide and a second layer 87 of polysilicon are formed. Finally, a groove 82' is dug by etching the second layer 87 of polysilicon as far as the stop layer 86.

Finally, it is evident that modifications and variations may be made to the inertial sensor described herein, without thereby departing from the scope of the present invention. In particular, the weakened regions can be defined both by side notches in the samples and by grooves extending between the side notches.

- 5 In addition, the weakened regions could be defined by through openings that traverse the samples, instead of by side notches.
